INTRODUCTION

There is increasing interest in the study of the relationship between religiosity/spirituality (R/S) and health, fostered by the finding that individuals who regularly attend religious services [1–9] have a reduction in overall mortality of almost 20%. The evidence for the possible association between R/S and reduced cardiovascular risk, however, is less consistent. Multiple prospective cohort and case-control studies [3,9–12] have linked R/S with reduced cardiovascular mortality and morbidity. A cross-sectional study conducted in a rural population in India has shown that men participating in prayer and yoga had a lower prevalence of coronary heart disease after adjustment for coronary risk factors [13]. A composite R/S measure (frequency of service attendance, prayer, and fasting) was inversely associated with acute coronary events in a recent case-control study [14] conducted in a predominantly Moslem and Christian population. On the other hand, other studies somewhat contradicted these results. Schnall et al. [8] reported a lack of association between several self-reported measures of R/S (religious affiliation, frequency of service attendance, and religious coping) and cardiovascular mortality in...
a large population of postmenopausal women. More frequent service attendance, prayer or meditation, and higher daily spiritual experience scores were not associated with reduced cardiovascular risk in a prospective cohort study involving more than 5000 healthy men and women enrolled in the Multi-Ethnic Study of Atherosclerosis (MESA) [15]. In a study of noninstitutionalized older adults, Colantonio et al. [16] reported that more frequent worship attendance was associated with a reduced risk of stroke in unadjusted models; in adjusted models, however, this association was no longer significant. Another study conducted in myocardial infarction survivors with depression and low social support did not show an association between daily spiritual experience scores, church attendance, or frequency of private spiritual activity and nonfatal cardiac events [17].

The link between frequency of individual private spiritual practices such as prayer, meditation, and devotional reading and cardiovascular health has been less frequently investigated at the population level compared with the more public aspects of R/S, namely, religious services attendance. Practices such as prayer or meditation are particularly interesting because their association with cardiovascular risk is less likely to be affected by variables—such as social support—that are known confounders of the association between service attendance and cardiovascular outcomes. Furthermore, unlike service attendance, the physiologic changes occurring during prayer and meditation have been extensively studied and consist of a decrease in sympathetic nervous system activity, oxygen consumption, respiratory rate, and minute ventilation [18]. Prayer or mantra recitation have been linked with higher levels of cardiac autonomic control [19] and increased baroreflex sensitivity [20], conditions that in turn have been associated with a reduced risk of cardiac arrhythmias and cardiac mortality [21–23]. A reduction in the activity of the sympathetic nervous system may be beneficial for patients with coronary heart disease, as shown by findings of increased exercise tolerance and delayed onset of electrocardiographic signs of ischemia in patients enrolled in a transcendental meditation program [24]. Similar results were shown by Benson et al [25], who reported that meditation reduced the number of premature ventricular contractions in these patients.

The primary aim of this study was to evaluate whether private spiritual activity (prayer, meditation, and reading of religious literature) is associated with a reduced incidence of fatal and nonfatal cardiovascular events in a large population of community-dwelling postmenopausal women enrolled in the Women's Health Initiative (WHI) Observational Study (OS). The WHI affords a unique opportunity to evaluate this association given its large sample size, as well as the adjudication of cardiovascular outcomes. Our study hypothesis was that women who report to engage in private spiritual activity, compared with women reporting no spiritual activity, would have a reduced cardiovascular risk.

The secondary aim was to assess whether the association may differ in women with a history of severe chronic diseases before the assessment of private spiritual activity compared with women without such history. This analysis was undertaken in light of the important role of R/S, including private spiritual activity, in coping with serious illness. This is illustrated by the fact that the proportion of people with serious illnesses (e.g., cancer) who report praying for their health (77%) [26] may be double the proportion in the general population (43%) [27]. Further, there is evidence [28] that the association between private spiritual activity and cardiovascular risk may differ depending on whether such activity is a longstanding, lifelong behavior or rather an episodic phenomenon elicited in response to stressful events or illness.

Despite the concerns raised in regard to the methodologic limitations and lack of direct clinical applications of the research in this field [29], the study of the role of R/S in the prevention of cardiovascular disease (CVD) may have important public health consequences if these practices are associated with a lower cardiovascular risk [30].

Methods

The WHI included a set of randomized clinical trials and a separate OS [29]. The OS, the focus of this analysis, was a large prospective cohort study conducted in 93,676 postmenopausal women ineligible or unwilling to participate in the clinical trials. To be eligible women had to be 50 to 79 years old, postmenopausal, and reside in the study recruitment area for at least 3 years after enrollment. Exclusion criteria were medical conditions predictive of a survival time of less than 3 years; conditions inconsistent with study participation such as alcoholism, drug dependency, mental illness, and dementia; and enrollment in another study. All participants provided written, informed consent according to the human subjects' protection oversight at the 40 participating sites. Recruitment (1994–1998) was conducted through mailings to eligible women from large mailing lists. Women were followed through 2005 as part of the original study and were offered the opportunity to continue for an additional 5 years in the WHI extension study. After obtaining informed consent, yearly questionnaires were administered by mail between 2005 and 2010.

All OS participants underwent a baseline visit including physical measurements (height, weight, blood pressure, heart rate, waist and hip circumferences), blood specimen collection, a medication/supplement inventory, and completion of medical, family/reproductive history, lifestyle/behavioral factors, and quality-of-life questionnaires. Follow-up included an on-site clinic visit 3 years after enrollment and annual mailings (a medical history update and questionnaires about lifestyle and dietary habits, demographics, hormone therapy, and psychosocial variables). The WHI OS outcomes were coronary heart disease, stroke, breast and colorectal cancer, osteoporotic fractures, diabetes, and total mortality.

Study population

Inclusion criteria for this secondary analysis were completion of the follow-up year 5 (YR5) assessments, and absence of self-reported CVD and any cardiovascular events through YR5. Women who did not consent to the WHI extension study were censored at the date of last follow-up.

Exposure

Time spent in private spiritual activity was assessed only at YR5 using a self-administered questionnaire completed approximately 5 years (1999–2003) after enrollment in the original study asking how often the participant spent time in the following activities: Prayer, meditation, or reading religious literature during the prior year. The possible answers were never, a few times per year, a few times per month, about once a week, a few times per week, every day.

Outcome

The outcome for this analysis was fatal and nonfatal incident cardiovascular events, a cumulative endpoint defined as the first occurrence of nonfatal angina, myocardial infarction, congestive heart failure, coronary and carotid revascularization procedures, stroke, transient ischemic attack, peripheral arterial disease, and any adjudicated fatal cardiovascular event. Outcomes were identified by self-report on the medical history update or by
Covariates and other variables of interest

Covariates were selected based on the literature and/or whether they were associated with frequency of private spiritual activity, cardiovascular events, or both. Whenever possible, we used information collected at the same time (YR5) as frequency of private spiritual activity. When variables had not been collected at YR5 we used covariates collected at YR3 or at baseline, whichever was closest in time. Except for body mass index, all covariates were collected by means of self-administered questionnaires and included age, race/ethnicity (American Indian or Alaskan Native, Asian or Pacific Islander, Black or African-American, Hispanic/Latino, White, other), marital status (never married, married or in marriage-like relationship, widowed, divorced/separated), total years of education, and annual income (<$10,000; $10,000–19,999; $20,000–34,999; $35,000–49,999; $50,000–74,999; $75,000–99,999; $100,000–149,999; >$150,000; does not know). Risk factors for CVD included history of hypertension and diabetes, family history, smoking (ever, never, current), and body mass index (kg/m² calculated from direct measurements of height and weight performed at YR3). Cholesterol levels were not measured in the entire OS cohort so history of elevated cholesterol requiring pharmacologic treatment was used as a proxy. Physical activity was calculated as energy expenditure from recreational physical activity (total metabolic equivalent task-hours per week). Alcohol intake was measured as the number of servings of alcohol per week. Psychosocial variables included social support (from the Medical Outcomes Study) [33]; physical functioning, emotional well-being, and satisfaction with quality of life (Medical Outcome Study 36-Item Health Survey) [34]; and depression (assessed using the shortened version of the Center for Epidemiological Studies Depression Scale) [35].

History of severe chronic diseases was defined as a self-reported history of severe noncardiovascular comorbidities before YR5, including diabetes, liver disease, dialysis, asthma, emphysema, lupus, Alzheimer disease, multiple sclerosis, Parkinson disease, and amyotrophic lateral sclerosis, as well as all adjudicated cancer outcomes (except nonmelanoma skin cancers).

Statistical analysis

We used descriptive statistics to describe the baseline characteristics of the study population across categories of frequency of private spiritual activity. Analysis of variance F and independent \( \chi^2 \) tests were used to evaluate differences. The association between private spiritual activity (categorized as daily, once or more per week, less than once a week, and never) and cardiovascular events was evaluated using univariate and multivariate Cox proportional hazards regression models. We tested the assumption of the proportional hazard model by entering time dependent covariates (HR) with 95% confidence intervals. \( P < .05 \) was considered significant. All statistical analyses were performed using SAS/STAT version 9.2 (SAS Institute, Cary, NC).

Results

Figure 1 (STrengthening the Reporting of Observational studies in Epidemiology [STROBE] diagram) [36] shows the flow of patients through this study. Of the original cohort of 93,676 women enrolled in the OS, 61,370 met the eligibility criteria for this study. Owing to missing information on covariates included in multivariate models, 17,662 women were excluded from the final analysis. These women tended to be more frequently African American (9% vs. 5.4%) or Hispanic (5% vs. 2.8%), less educated (postgraduate education, 28.3% vs. 34.6%) and more frequently current smokers (5% vs. 3.7%) compared with subjects included in the analysis, but had otherwise similar characteristics with regard to spiritual practices and cardiovascular events (no spiritual practice, excluded vs. included, 17.2% vs. 17.9%; cardiovascular events, 6.3% vs. 5.8%).

The baseline characteristics of the study population are shown in Table 1. Women with higher frequency of private spiritual activity tended to be older, less educated, of African American ancestry, widowed or never married, and of lower socioeconomic status; they also reported lower functional status scores. The prevalence of a diagnosis of a severe chronic disease before YR5 as well as of most risk factors for CVD was also higher in women reporting more frequent private spiritual activity. Specifically, these women were more frequently obese, used cholesterol-lowering drugs more often, had a history of hypertension or diabetes and reported lower levels of physical activity. The only exception among coronary risk factors was smoking, because women frequently engaging in private spiritual activity were less likely to be current or former smokers. Alcohol intake also was significantly lower among those with a higher frequency of private spiritual activity. Finally, women with more frequent spiritual
practice had slightly better emotional well-being, higher social support, and a slightly lower prevalence of depression and anti-depressants use.

The median duration of follow-up was 7 years, during which 2554 cardiovascular events were observed (402 fatal). Age-adjusted models (Table 2, Model 1) showed that women who reported weekly and daily spiritual practice had a higher risk of cardiovascular events compared with women who never engaged in such activity (HR, 1.16 [95% CI, 1.03–1.30]) compared with women who did not report such activity. Further adjustment for psychosocial measures (model 5) and depression and emotional well-being (model 6) did not modify these associations. We also fitted a model adjusting for presence/absence of severe chronic diseases in addition to the variables included in model 2 (age, ethnicity, marital status, income, and education), but the association between cardiovascular events and spiritual practice was not altered (HR, 1.08 [95% CI, 0.95–1.23] for weekly vs. never).

**Table 1**

Characteristics of the study population, by frequency of private spiritual activity.
The analysis included women with complete data, cardiovascular mortality and cardiovascular events (n = 43,708).

Hazard ratios (HR) are reported with 95% confidence intervals.

Model 1, age-adjusted. Model 2, adjusted for age, ethnicity, marital status, income, and education. Model 3, model 2 plus physical activity (MET-hours), smoking status, alcohol servings/week. Model 4, model 3 plus body mass index, high cholesterol, hypertension, diabetes, and family history of myocardial infarction. Model 5, model 4 plus physical functioning, satisfaction with quality of life, social support. Model 6, model 5 plus CES-D and emotional well-being scores.

Subgroup analysis

Table 3 and Figure 2 show the results of the subgroup analysis by presence/absence of self-reported severe chronic diseases before YR5. Results indicate that the presence of severe chronic diseases was not an effect modifier (P = .6449).

Discussion

In previous population-based studies, more frequent worship participation [3,10] or, among Jews, adherence to orthodox practices and teachings [11,12], were found to be associated with a reduced cardiovascular risk. In our study of a large population of community-dwelling postmenopausal women, however, when we focused our attention on frequency of meditation, prayer, or reading of religious texts, we found that this dimension of R/S was not associated with a reduced cardiovascular risk; in fact, women reporting daily private spiritual activity had a higher risk of cardiovascular events compared with women who reported no private spiritual activity.

The present study was designed to follow-up on the findings of a previous investigation conducted in the WHI-OS [8], which did not detect an association between baseline measures of R/S and cardiovascular risk; however, these measures did not include private spiritual activity. The relationship between multiple measures of R/S (worship attendance, prayer, and daily spiritual experience scores) and cardiovascular risk factors and events has been studied among more than 5000 participants aged 45 to 84 years in the MESA study [15]. As in the present study, higher levels of R/S, including prayer, were associated with greater risk of obesity and decreased risk of drinking and smoking. Unlike the results reported herein, among the MESA participants there was no significant association between frequency of prayer and cardiovascular risk. Our study, however, had a larger sample size and a longer duration of follow-up; in addition, even in the MESA analysis, the point estimate in the group with daily private spiritual activity, although not significant, indicated an increased risk of cardiovascular events in the more religiously involved.

A possible explanation for our findings would be confounding by the presence of severe chronic comorbidities; in fact, the prevalence of severe, chronic comorbidities before YR5 was associated with a higher frequency of private spiritual activity (Table 1). In multivariate models, however, the presence of severe chronic disease was not a confounder. Although the interaction term was not significant, the results of the stratified analysis nevertheless suggest that women with a prior diagnosis of severe, chronic diseases likely drive the association between private spiritual activity and increased cardiovascular risk. Similar findings have been reported in another study conducted in an elderly population [28] in which the protective association between private spiritual activity and reduced overall mortality was detected only in individuals without impairment in activities of daily living, and was not detected in the cohort reporting such a condition.

Our results are not consistent with some of the previous published studies indicating that R/S is associated with a lower cardiovascular risk [9]. It seems, however, that our knowledge about the link between R/S and cardiovascular health is far from being conclusive for several reasons. For example, studies that have detected a protective association between R/S and cardiovascular risk measured very different aspects of the R/S experience. Some researchers measured worship attendance only [3,10], whereas others measured self-reported religiosity within specific religious groups [11,12]. Studies also differed as to whether they adjusted for coronary risk factors (i.e., diabetes, high cholesterol) and other

CD = chronic disease history; CV = cardiovascular.
P < .0001 for differences in CV events by presence/absence of CDH.
P = .6449 for interaction term added to model 6.
The analysis included women with complete data (n = 43,708).
Hazard ratios (HR) are reported with 95% confidence intervals (CI).
Chronic disease history is defined as history of chronic disease reported before year 5 including cancer (except nonmelanoma skin cancer), diabetes, liver disease, kidney dialysis, asthma, emphysema, lupus, Alzheimer disease, multiple sclerosis, Parkinson disease, amyotrophic lateral sclerosis. Data from The Women’s Health Initiative Study Group [31].
variables that may confound the association between R/S and cardiovascular mortality. The only studies extensively adjusting for coronary risk factors and reporting an association between R/S (defined as being orthodox vs. secular) and reduced risk of cardiovascular mortality or acute myocardial infarction were conducted in a Jewish population in Israel [1,11,12]. Orthodox Judaism, however, is somewhat unique in that it regulates every aspect of life as opposed to a later stage, when individuals may turn to religion as a coping mechanism in the face of declining health and advancing age [28,39]. Finally, the duration of follow-up differed greatly among studies; studies reporting a protective effect usually had a longer follow-up duration [3,10,11].

This study has several strengths: First, a relatively long duration of follow-up; second, extensive adjustment for coronary risk factors, and demographic and psychosocial variables; third, a relatively understudied population (women); and fourth, the validation of cardiovascular outcomes. The limitations of this analysis include the assessment of private spiritual activity as an aggregate only, with the resulting inability to assess associations between specific activities (i.e., meditation and/or prayer vs. reading of religious texts) and cardiovascular events; and the collection of private spiritual activity data only at YRS. Furthermore, some covariates were not collected at the same time point (YRS5) as the spirituality activity assessment, and we had to use baseline or YR3 covariates. Residual confounding (in particular regarding coronary risk factors such as blood pressure and serum lipid levels that were not directly measured) as well as selection bias (owing to the large number of women excluded) are additional limitations of this analysis. Also, we cannot rule out the possible contribution of survivor bias (e.g., women with lower levels of private spirituality activity not surviving long enough to be included in the current analysis) to our findings. Finally, results are not generalizable to younger or male populations, and to women that were excluded from participation in the parent study (i.e., women with alcoholism, drug dependency, mental illness, and dementia).

In conclusion, our results confirm recent indications that higher R/S does not prevent fatal and nonfatal cardiovascular events [8,15], at least in older female populations. Further research involving younger and healthier populations is needed to achieve a better understanding of the role of R/S in the prevention of cardiovascular risk.
